Stream Bioassessment
Bound Brook, New Jersey
January 7, 1993

Participating Personnel:

U.S. Environmental Protection Agency James Kurtenbach, Aquatic Biologist Michael Chadwick, Student Trainee

Report Prepared by:

James Kurtenbach, Aquatic Biologist Ambient Monitoring Section

Approved for the Director by:

Richard D. Spear, Chief Surveillance and Monitoring Branch Stream: Bound Brook (South Plainfield to Middlesex)

Objective:

Biological sampling using rapid bioassessment procedures, which utilizes benthic macroinvertebrate communities to screen water quality, was conducted at three locations on Bound Brook on June 12, 1992. Macroinvertebrate samples were taken in riffle areas using the kick net procedures described in appendix i. Organisms and debris collected were placed in one quart sample jars containing alcohol and preserved for lab processing as outlined in appendix I. All macroihvertebrates were identified to the family level, with the exception of oligochaeta (worms) and gastropoda (snails). All organism identifications and counts were recorded for each station. Water quality was evaluated using the following community measures: 1) total taxa richness, 2) EPT richness, 3) percent dominance, 4) percent EPT and 5) biotic index (See appendices II and III). Physical and chemical measurements for existing stream conditions were recorded on physical characterization/water quality field data sheets. Stream habitat condition was recorded on habitat assessment field sheets.

Findings and Conclusions:

water quality was assessed as severely impacted at station 1 and moderately impacted at stations 2 and 3. All five biological metrics used to assess the macroinvertebrate community at statibh 1 measured gross impairment. An increase in taxa richness was responsible for the slightly improved biological condition measured at both downstream locations. An impoundment located between stations 1 and 2 may serve as a trap for the downstream release of pollutants. This may be implicated as one reason for the slight water quality improvement. Additional studies using fish community assessments have also measured poor to fair water quality in Bound Brook.

Recommendations:

Intensive basin assessments utilizing biological and chemical parameters should be conducted to determine the pollutants responsible for the serious water quality degradation.

station 1: Upstream of Lakeview Ave

Total taxa richness: 2 (severely impacted)

EPT richness: 0 (severely impacted)

Percent dominance: 97 (severely impacted)

Percent EPT: 0 (severely impacted)

Biotic index: 7.94 (severely impacted)

Water Quality Assessment: severely impacted

Station 2: Downstream of Prospect Ave

Total taxa richness: 7 (moderately impacted)

EPT richness: 1 (severely impacted)

Percent dominance: 51 (moderately impacted)

Percent EPT: 0 (severely impacted)

Biotic index: 5.44 (moderately impacted)

Water Quality Assessment: moderately impacted

Station 3: Upstream of Hwy 28

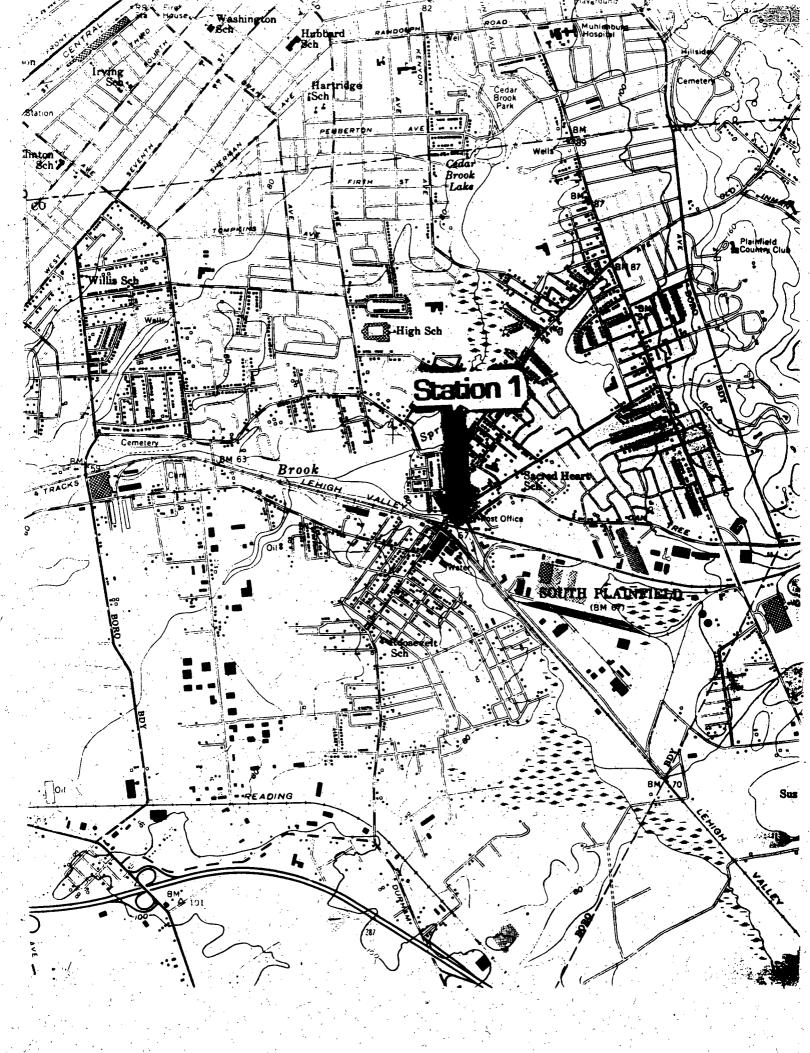

Total taxa richness: 7 (moderately impacted)

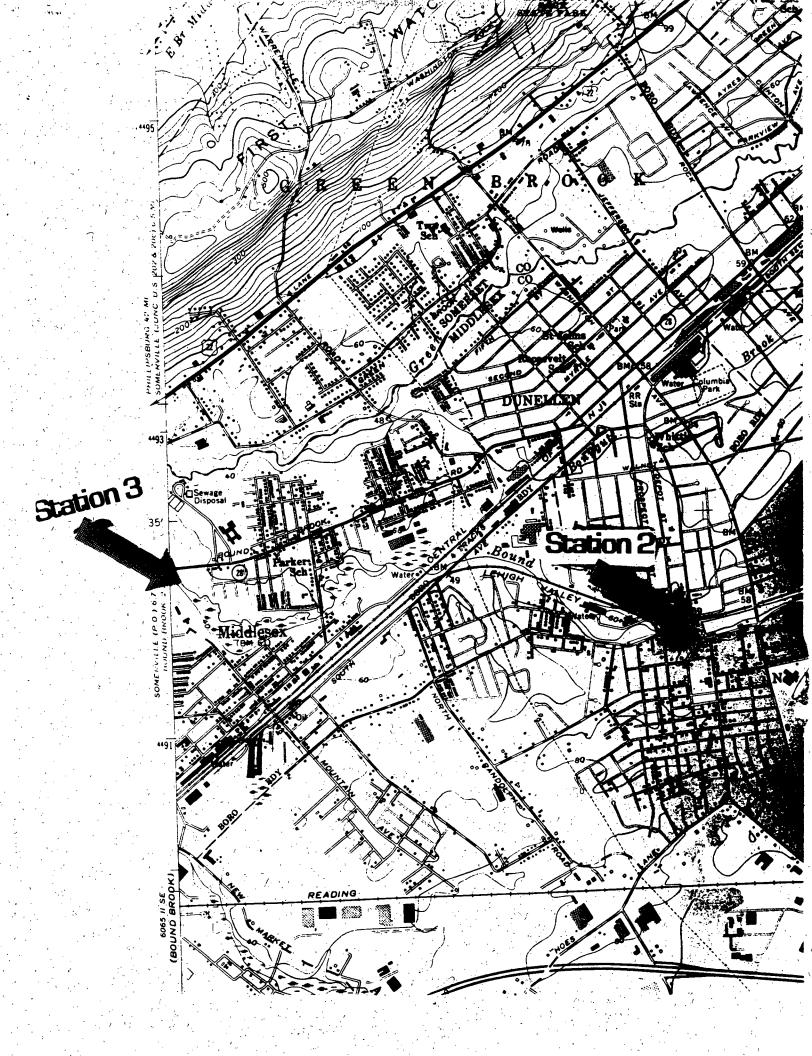

EPT richness: 1 (severely impacted)
Percent dominance: 34 (non-impacted)

Percent EPT: 0 (severely impacted)

Biotic index: 6.31 (severely impacted)

Water Quality Assessment: moderately impacted

Field Collection:

Riffle areas are the preferred sampling habitat. To assure comparability between stations sampled, riffle habitats with similar physical features should be selected. This must at a minimum include, substrate size, current velocity, depth and percent gyerhead canopy. Benthic macroinvertebrates are captured from rock substrates (small boulder and cobble) in riffle areas using a 8 % 18 kick net having a .800-.900 mm mesh size. The kick net is worked side to side and downstream for a 5 minute interval; during which the rock substrate is disturbed upstream. Sampling is confined to the mid-river portion of the riffle. All saupling is conducted during the period June through the first week of September. Macroinvertebrates and debris collected are their placed in a one quart sample jar and preserved with 70% ethyl alcohol containing 125 mg/l rose bengal dye.

When low gradient precludes streams from having riffle areas (e.g. central and southern NJ streams), sampling multiple habitats is required. A multi-habitat sample should consist of organiaas taken from instream woody debris (sticks and logs), streambars woody snags, depositional areas containing coarse particulats organic matter, aquatic vascular plants and sand/gravel bottom sediments. These physical habitat characteristics are typical for most wadable streams located in central and southern New Jersey. No time restrictions are required for collecting a multi-habitat sample, and some minimum level of effort is necessary to obtain a representative sample. The sampling typically requires 10 to 15 minutes of effort. Macroinvertebrates are collected similarly to those from riffle areas by placing the kick net downstream of the substrate being disturbed and allowing organisms to drift into the net.

Laboratory Processing:

Laboratory methods which utilize a 100-organism subsample were modified from Hilsenhoff (1982). Alcohol containing the sample is poured through a U.S. No. 30 sieve and the sample is placed in a grided glass baking. Care must be taken to assure the sample is homogenous in the dish to avoid bias. Grided sections (2"x2") are then choosen using random numbers until the first 100 organisms are removed. Organism counts are made using a hand recorder. Sorting is always conducted under good light conditions. This includes a light box under the dish and a overhead lamp. When sorting is complete, the i00-organism samples are placed in vials and retained for future identification. All organism identifications are recorded on macroinvertebrate data sheets.

Physical and Chemical Parameters:

Physical and chemical measurements of existing stream conditions are recorded on physical characterization/water quality field data sheets taken from Plafkln et. al. (1989). Additional notes on the absence and presence of aquatic macrophyte, algae, fish species and other pertinent information should be recorded. When impairment is obseved, an impairment assessment sheet taken from Plafkln et. al. (1989) should be filled out.

Habitat Assessment:

A habitat assessment is conducted at every sampling station and all information is recorded on field sheets. Such assessments provide valuable information on probable causes of impairment to instream biota, when water quality parameters do not indicate any limitations. The habitat assessment consists of an evaluation of the following physical features: substrate, channel morphology and streamside cover. Each of these groups are scored and sumed to produce a total score which is assigned a habitat quality category; excellent, good, fair or poor.

Community Metric Description:

Once taxa from each sample have been identified and counted, various community measures are used to evaluate biological integrity. Community analysis is accomplished by using the following biometrics: 1) total taxa richness, 2) EPT taxa richness, 3) percent dominance, 4) percent EPT and 5) Hilsenhoff biotic index. Community metric criteria have been established for three condition categories of water quality; non-impacted, moderately impacted and severely impacted. Numeric criteria for each condition category were established by characterizing macroinvertebrate community structure and function found in non-impacted and severely impacted stream systems. A description of each biometric used to measure instream biological condition is presented below.

1. Total taxa richness:

This metric is simply a measure of the total number of macroinvertebrate taxa identified from a sample collection. A reduction in taxa richness may indicate a pollutant stressor (organic enrichment, toxics, etc.). Taxa which are least tolerant of environmental change are the first to become absent with increased water degradation.

2. EPT richness:

This metric measures the total number of Ephemeropteran (mayflies), Plecopteran (stoneflles) and Trichopteran (caddisflies) taxa in a sample collection. These aquatic insect groups are very sensitive to pollution induced environmental change, and so their presence or absence is a good indicator of water quality.

3. Biotic Index:

This metric measures the relative tolerance of benthic macroinvertebrates to organic enrichment. Species or families are assigned a score of 0 (intolerant) to 10 (tolerant) Hilsenhoff (1982,1988) and Bode (1988). Additional tolerance values for macroinvertebrates not listed in Hilsenhoff (1982,1988) and Bode (1988) are included in Appendix IV. The biotic index is calculated by multipling the number of each species by their assigned tolerance score, sumlng these, and then dividing by the total number of individuals in the sample. The biotic index was designed to measure impairment resulting from organic waste loading rather than inorganic inputs (e.g. heavy metals or other toxic substances), so caution should be exercized when applying this index.

4. Percent Dominance:

This metric measures relative balance within the macroinvertebrate community. Healthy communities are characterized by a diverse number of relatively intolerant taxa comprised of different functional groups having abundances somewhat proportional to each other. As a system becomes degraded, certain taxa or taxa assemblages most tolerant of the perturbation become abundant, while intolerant taxa and certain functional groups become reduced. For example, an increased abundance of intermediate tolerant filter feeders is often associated with increased organic enrichment resulting from some organic waste load. Dominance may also provide an endpoint to measure impairment caused by toxics. For example, certain taxa within the Chironomidae family become abundant relative to EPT when concentrations of heavy metals increase (Clements et. al. 1988).

5. Percent EPT:

This metric provides a good measure of numeric abundance for three sensitive groups of aquatic insects. A good representation of mayflies, stoneflles and caddisflies is usually associated with good water quality. Abundances of taxa within these groups often decreases with only sutble environmental changes caused by organic and/or toxic pellutants.

∵ ਹ•	Uligenmoni procie tudey			

Biological Condition	Total Score
Non-impacted	24-30
Moderately impacted	9-21
Severely impacted	0-6

Condition Category

Non-impacted: Benthic community comparable to other undisturbed streams within the region. A community characterized by a maximum taxa richness, balanced taxa groups and good representation of intolerant individuals.

Moderately impacted: Macroinvertebrate richness is reduced, in particular EPT taxa. Taxa composition changes result in reduced community balance and intolerant taxa become absent.

Severely impacted: A dramatic change in the benthic community has occurred. Macroinvertebrates are dominated by a few taxa which are very abundant. Tolerant taxa are the only individuals present.

a - Based on 100 organism subsamples

* Not including the Hydropsychid family
